For our families and loved ones

Acknowledgements

First of all, many thanks to our families and loved ones that supported us during the writing of this thesis. Secondly, thank you professors Zhang⁴, Annaert⁵ and De Ceuster⁶ for the valuable insights during courses you have given us in preparation of this thesis, the dozens of assignments using the R language and the many questions answered this year. We must be grateful for the classes of R programming by prof Zhang.

Secondly, we have to thank the developer of the software we used for our thesis. A profuse thanks to Allaire, the founder and CEO of RStudio. Thanks for making data science easier, more accessible and fun. We must also be grateful to the inventors of “Markdown”, “Pandoc”, “knitr”, “bookdown”, “thesisdown”. Then, we must say thanks to Ulrik Lyngs who made it a bit easier to work together in R with a pre-build template for the university of Oxford, also without which this thesis could not have been written in this format (Lyngs 2019).

Finally, we thank Alexios Ghalanos for making the implementation of GARCH models integrated in R via his package “rugarch”. By doing this, he facilitated the process of understanding the whole process and doing the analysis for our thesis.

Introduction

119 A general assumption in finance is that stock returns are normally distributed.
120 However, various authors have shown that this assumption does not hold in
121 practice: stock returns are not normally distributed (Among which Theodossiou
122 2000; Subbotin 1923; Theodossiou 2015). For example, Theodossiou (2000) mentions
123 that “empirical distributions of log-returns of several financial assets exhibit strong
124 higher-order moment dependencies which exist mainly in daily and weekly log-
125 returns and prevent monthly, bimonthly and quarterly log-returns from obeying the
126 normality law implied by the central limit theorem. As a consequence, price changes
127 do not follow the geometric Brownian motion.” So in reality, stock returns exhibit
128 fat-tails and peakedness (Officer 1972), these are some of the so-called stylized facts
129 of returns.

130

131 Additionally, a point of interest is the predictability of stock prices. Fama (1965)
132 explains that the question in academic and business circles is: “To what extent can
133 the past history of a common stock’s price be used to make meaningful predictions
134 concerning the future price of the stock?”. There are two viewpoints towards the
135 predictability of stock prices. Firstly, some argue that stock prices are unpredictable
136 or very difficult to predict by their past returns (i.e. have very little serial correlation)
137 because they simply follow a Random Walk process (Fama 1970). On the other hand,
138 Lo & MacKinlay mention that “financial markets *are* predictable to some extent
139 but far from being a symptom of inefficiency or irrationality, predictability is the oil
140 that lubricates the gears of capitalism”. Furthermore, there is also no real robust
141 evidence for the predictability of returns themselves, let alone be out-of-sample
142 (Welch and Goyal 2008). This makes it difficult for corporations to manage market

143 risk, i.e. the variability of stock prices.

144
145 Risk, in general, can be defined as the volatility of unexpected outcomes (Jorion
146 2007). The measure Value at Risk (VaR), developed in response to the financial
147 disaster events of the early 1990s, has been very important in the financial world.
148 Corporations have to manage their risks and thereby include a future risk mea-
149 surement. The tool of VaR has now become a standard measure of risk for many
150 financial institutions going from banks, that use VaR to calculate the adequacy of
151 their capital structure, to other financial services companies to assess the exposure
152 of their positions and portfolios. The 5% VaR can be informally defined as the
153 maximum loss of a portfolio, during a time horizon, excluding all the negative events
154 with a combined probability lower than 5% while the Conditional Value at Risk
155 (CVaR) can be informally defined as the average of the events that are lower than
156 the VaR. Bali, Mo, et al. (2008) explains that many implementations of the CVaR
157 have the assumption that asset and portfolio's returns are normally distributed but
158 that it is an inconsistency with the evidence empirically available which outlines
159 a more skewed distribution with fatter tails than the normal. This lead to the
160 conclusion that the assumption of normality, which simplifies the computation of
161 VaR, can bring to incorrect numbers, underestimating the probability of extreme
162 events happening.

163
164 This paper has the aim to replicate and update the research made by Bali, Mo,
165 et al. (2008) on US indexes, analyzing the dynamics proposed with a European
166 outlook. The main contribution of the research is to provide the industry with a
167 new approach to calculating VaR with a flexible tool for modeling the empirical
168 distribution of returns with higher accuracy and characterization of the tails.

169
170 The paper is organized as follows. Chapter 1 discusses at first the alternative
171 distribution than the normal that we are going to evaluate during the analysis
172 (Student's t-distribution, Generalized Error Distribution, Skewed t-distribution,

Introduction

173 Skewed Generalized Error Distribution, Skewed Generalized t-distribution), then the
174 discrete time GARCH models used (GARCH, IGARCH, EGARCH, GJRGARCH,
175 NAGARCH, TGARCH, TSGARCH or AVGARCH and EWMA) are presented as
176 extensions of the Engle (1982) 's ARCH model. Chapter 2 describes the dataset
177 used and the methodology followed in modeling the volatility with the GARCH
178 model by Bollerslev (1986) and with its refinements using Maximum likelihood
179 estimation to find the distribution parameters. Then a description is given of how
180 are performed the control tests (un- and conditional coverage test, dynamic quantile
181 test) used in the paper to evaluate the performances of the different GARCH models
182 and underlying distributions. In chapter 3, findings are presented and discussed,
183 in chapter 4 the findings of the performed tests are shown and interpreted and in
184 chapter 5 the investigation and the results are summarized.

Volatility is unobservable. We can only ever estimate and forecast volatility, and this only within the context of an assumed statistical model. So there is no absolute ‘true’ volatility: what is ‘true’ depends only on the assumed model...

Moreover, volatility is only a sufficient statistic for the dispersion of the returns distribution when we make a normality assumption. In other words, volatility does not provide a full description of the risks that are taken by the investment unless we assume the investment returns are normally distributed.

— Alexander (2008) in *Market Risk Analysis Practical Financial Econometrics*

Literature review

1.1 Stylized facts of returns

When analyzing returns as a time-series, we look at log returns. The log returns are similar to simple returns so the stylized facts of returns apply to both. One assumption that is made often in financial applications is that returns are iid, or independently and identically distributed, another is that they are normally distributed. Are these valid assumptions? Below the stylized facts¹ following Annaert (2021) for returns are given.

- Returns are *small and volatile* (with the standard deviation being larger than the mean on average).
- Returns have very little serial correlation as mentioned by for example Bollerslev (1987).
- Returns exhibit conditional heteroskedasticity, or *volatility clustering*. This effect goes back to Mandelbrot (1963). There is no constant variance (homoskedasticity), but it is time-varying. Bollerslev (1987) describes it as “rates of return data are characterized by volatile and tranquil periods”. Alexander (2008) says this will have implications for risk models: following a large shock

¹Stylized facts are the statistical properties that appear to be present in many empirical asset returns (across time and markets)

1. Literature review

203 to the market, the volatility changes and the probability of another large
204 shock is increased significantly.

- 205 • Returns also exhibit *asymmetric volatility*, in that sense volatility increases
206 more after a negative return shock than after a large positive return shock.
207 This is also called the *leverage effect*. Alexander (2008) mentions that this
208 leverage effect is pronounced in equity markets: usually there is a strong
209 negative correlation between equity returns and the change in volatility.
- 210 • Returns are *not normally distributed* which is also one of the conclusions
211 by Fama (1965). Returns have tails fatter than a normal distribution
212 (leptokurtosis) and thus are riskier than under the normal distribution. Log
213 returns **can** be assumed to be normally distributed. However, this will be
214 examined in our empirical analysis if this is appropriate. This makes that
215 simple returns follow a log-normal distribution, which is a skewed density
216 distribution. A good summary is given by Alexander (2008) as: “In general,
217 we need to know more about the distribution of returns than its expected
218 return and its volatility. Volatility tells us the *scale* and the mean tells us the
219 *location*, but the dispersion also depends on the *shape* of the distribution.
220 The best dispersion metric would be based on the entire distribution function
221 of returns.”

222 Firms holding a portfolio have a lot of things to consider: expected return of a
223 portfolio, the probability to get a return lower than some threshold, the probability
224 that an asset in the portfolio drops in value when the market crashes. All the
225 previous requires information about the return distribution or the density function.
226 What we know from the stylized facts of returns that the normal distribution is
227 not appropriate for returns. In appendix part A we summarize some alternative
228 distributions (T, GED, ST, SGED, SGT) that could be a better approximation
229 of returns than the normal one.

1.2 Volatility modeling

1.2.1 Rolling volatility

When volatility needs to be estimated on a specific trading day, the method used as a descriptive tool would be to use rolling standard deviations. Engle (2001) explains the calculation of rolling standard deviations, as the standard deviation over a fixed number of the most recent observations². Engle regards this formulation as the first ARCH model.

1.2.2 ARCH model

Autoregressive Conditional Heteroscedasticity (ARCH) models, proposed by Engle (1982), was in the first case not used in financial markets but on inflation. Since then, it has been used as one of the workhorses of volatility modeling. To fully capture the logic behind GARCH models, the building blocks are examined in the first place. There are three building blocks of the ARCH model: returns, the innovation process and the variance process (or volatility function), written out for an ARCH(1) in respectively equation (1.1), (1.2) and (1.3). Returns are written as a constant part (μ) and an unexpected part, called noise or the innovation process. The innovation process is the volatility (σ_t) times z_t , which is an independent identically distributed random variable with a mean of 0 (zero-mean) and a variance of 1 (unit-variance). The independent (iid), notes the fact that the z -values are not correlated, but completely independent of each other. The distribution is not yet assumed. The third component is the variance process or the expression for the volatility. The variance is given by a constant ω , plus the random part which depends on the return shock of the previous period squared (ε_{t-1}^2). In that sense when the uncertainty or surprise in the last period increases, then the variance

²For example, for the past month it would then be calculated as the equally weighted average of the squared deviations from the mean (i.e. residuals) from the last 22 observations (the average amount of trading or business days in a month). All these deviations are thus given an equal weight. Also, only a fixed number of past recent observations is examined.

1. Literature review

254 becomes larger in the next period. The element σ_t^2 is thus known at time $t - 1$, while
 255 it is a deterministic function of a random variable observed at time $t - 1$ (i.e. ε_{t-1}^2).

$$y_t = \mu + \varepsilon_t \quad (1.1)$$

$$\varepsilon_t = \sigma_t \times z_t, \text{ where } z_t \stackrel{iid}{\sim} (0, 1) \quad (1.2)$$

$$\sigma_t^2 = \beta_0 + \beta_1 \times \varepsilon_{t-1}^2 \quad (1.3)$$

256 From these components we could look at the conditional moments (or expected
 257 returns and variance). We can plug in the component σ_t into the conditional mean
 258 innovation ε_t and use the conditional mean innovation to examine the conditional
 259 mean return. In equation (1.4) and (1.5) they are derived. Because the random
 260 variable z_t is distributed with a zero-mean, the conditional expectation is 0. As
 261 a consequence, the conditional mean return in equation (1.5) is equal to the
 262 unconditional mean in the most simple case. But variations are possible using
 263 ARMA (eg. AR(1)) processes.

$$\mathbb{E}_{t-1}(\varepsilon_t) = \mathbb{E}_{t-1}(\sqrt{\beta_0 + \beta_1 \times \varepsilon_{t-1}^2} \times z_t) = \sigma_t \mathbb{E}_{t-1}(z_t) = 0 \quad (1.4)$$

$$\mathbb{E}_{t-1}(y_t) = \mu + \mathbb{E}_{t-1}(\varepsilon_t) = \mu \quad (1.5)$$

264 For the conditional variance, knowing everything that happened until and including
 265 period $t - 1$ the conditional innovation variance is given by equation (1.6). This
 266 is equal to σ_t^2 , while the variance of z_t is equal to 1. Then it is easy to derive
 267 the conditional variance of returns in equation (1.7), that is why equation (1.3)
 268 is called the variance equation.

$$var_{t-1}(\varepsilon_t) = \mathbb{E}_{t-1}(\varepsilon_t^2) = \mathbb{E}_{t-1}(\sigma_t^2 \times z_t^2) = \sigma_t^2 \mathbb{E}_{t-1}(z_t^2) = \sigma_t^2 \quad (1.6)$$

$$var_{t-1}(y_t) = var_{t-1}(\varepsilon_t) = \sigma_t^2 \quad (1.7)$$

269 The unconditional variance is also interesting to derive, while this is the long-run
 270 variance, which will be derived in equation (1.11). After deriving this using the
 271 law of iterated expectations and assuming stationarity for the variance process, one
 272 would get equation (1.8) for the unconditional variance, equal to the constant c
 273 and divided by $1 - \beta_1$, the slope of the variance equation.

$$\sigma^2 = \frac{\beta_0}{1 - \beta_1} \quad (1.8)$$

274 This leads to the properties of ARCH models: Stationarity³ condition for variance:
 275 $\beta_0 > 0$ and $0 \leq \beta_1 < 1$. But also, zero-mean innovations and uncorrelated
 276 innovations. Thus a weak white noise process ε_t . The unconditional 4th moment,
 277 kurtosis $\mathbb{E}(\varepsilon_t^4)/\sigma^4$ of an ARCH model is given by equation (1.9). This term is
 278 larger than 3, which implicates fat-tails.

$$3 \frac{1 - \beta_1^2}{1 - 3\beta_1^2} \quad (1.9)$$

279 Another property of ARCH models is that it takes into account volatility clustering.
 280 Because we know that $var(\varepsilon_t) = \mathbb{E}(\varepsilon_t^2) = \sigma^2 = \omega/(1 - \alpha_1)$, we can plug in β_0
 281 for the conditional variance $var_t(\varepsilon_{t+1}) = \mathbb{E}(\varepsilon_{t+1}^2) = \sigma_{t+1}^2 = c + \alpha_1 \times \varepsilon_t^2$. Thus it
 282 follows that equation (1.10) displays volatility clustering. If we examine the RHS,
 283 as $\alpha_1 > 0$ (condition for stationarity), when shock ε_t^2 is larger than what you
 284 expect it to be on average σ^2 the LHS will also be positive. Then the conditional

³Stationarity implies that the series on which the ARCH model is used does not have any trend and has a constant expected mean. Only the conditional variance is changing.

1. Literature review

285 variance will be larger than the unconditional variance. Briefly, large shocks will
286 be followed by more large shocks.

$$\sigma_{t+1}^2 - \sigma^2 = \alpha_1 \times (\varepsilon_t^2 - \sigma^2) \quad (1.10)$$

287 Excess kurtosis can be modeled, even when the conditional distribution is assumed
288 to be normally distributed. The third moment, skewness, can be introduced using
289 a skewed conditional distribution as we saw in part A. The serial correlation for
290 squared innovations is positive if fourth moment exists (equation (1.9), this is
291 volatility clustering once again.

292 How will then the variance be forecasted? Well, the conditional variance for the
293 k -periods ahead, denoted as period $T + k$, is given by equation (1.11). This can
294 already be simplified, while we know that $\sigma_{T+1}^2 = \omega + \alpha_1 \times \varepsilon_T^2$ from equation (1.3).

$$\begin{aligned} \mathbb{E}_T(\varepsilon_{T+k}^2) &= \omega \times (1 + \alpha_1 + \dots + \alpha^{k-2}) + \alpha^{k-1} \times \sigma_{T+1}^2 \\ &= \omega \times (1 + \alpha_1 + \dots + \alpha^{k-1}) + \alpha^k \times \sigma_T^2 \end{aligned} \quad (1.11)$$

295 It can be shown that then the conditional variance in period $T+k$ is equal to equation
296 (1.12). The LHS is the predicted conditional variance k -periods ahead above its
297 unconditional variance, σ^2 . The RHS is the difference current last-observed return
298 residual ε_T^2 above the unconditional average multiplied by α_1^k , a decreasing function
299 of k (given that $0 \leq \alpha_1 < 1$). The further ahead predicting the variance, the closer
300 α_1^k comes to zero, the closer to the unconditional variance, i.e. the long-run variance.

$$\mathbb{E}_T(\varepsilon_{T+k}^2) - \sigma^2 = \alpha_1^k \times (\varepsilon_T^2 - \sigma^2) \quad (1.12)$$

301 1.2.3 Univariate GARCH models

302 An improvement of the ARCH model is the Generalized Autoregressive Conditional
303 Heteroscedasticity (GARCH)⁴. This model and its variants come in to play because

⁴*Generalized* as it is a generalization by Bollerslev (1986) of the ARCH model of Engle (1982).
Autoregressive, as it is a time series model with an autoregressive form (regression on itself).

of the fact that calculating standard deviations through rolling periods, gives an equal weight to distant and nearby periods, by such not taking into account empirical evidence of volatility clustering, which can be identified as positive autocorrelation in the absolute returns. GARCH models are an extension to ARCH models, as they incorporate both a novel moving average term (not included in ARCH) and the autoregressive component. Furthermore, a second extension is changing the assumption of the underlying distribution. As already explained, the normal distribution is an unrealistic assumption, so other distributions which are described in part A will be used. As Alexander (2008) explains, this does not change the formulae of computing the volatility forecasts but it changes the functional form of the likelihood function⁵. An overview (of a selection) of investigated GARCH models is given in the following table.

Table 1.1: GARCH models, the founders

Author(s)/user(s)	Model
Engle (1982)	ARCH model
Bollerslev (1986)	GARCH model
Bollerslev (1986)	IGARCH model
Nelson (1991)	EGARCH model
Glosten et al. (1993)	GJRGARCH model
Engle and Ng (1993)	NAGARCH model
Zakoian (1994)	TGARCH model
Taylor (1986) and Schwert (1989)	TSGARCH (or AVGARCH) model
Morgan Guaranty Trust Company (1996)	EWMA or RiskMetrics model

1.3 ACD models

An extension to GARCH models was proposed by Hansen (1994), the autoregressive conditional density estimation model (referred to as ACD models, sometimes ARCD). It focuses on time variation in higher moments (skewness and kurtosis), because the degree and frequency of extreme events seem to be not expected by

Conditional heteroscedasticity, while time variation in conditional variance is built into the model (Alexander 2008).

⁵which makes the maximum likelihood estimation explained in part 2.2.1 complex with more parameters that have to be estimated.

1. Literature review

traditional models. Some GARCH models are already able to capture the dynamics by relying on a different unconditional distribution than the normal distribution (for example skewed distributions like the SGED, SGT), or a model that allows to model these higher moments. However, Ghalanos (2016) mentions that these models also assume the shape and skewness parameters to be constant (not time varying). As Ghalanos mentions: “the research on time varying higher moments has mostly explored different parameterizations in terms of dynamics and distributions with little attention to the performance of the models out-of-sample and ability to outperform a GARCH model with respect to VaR.” Also one could question the marginal benefits of the ACD, while the estimation procedure is not simple (nonlinear bounding specification of higher moment distribution parameters and interaction). So, are skewness (skewness parameter) and kurtosis (shape parameters) time varying? The literature investigating higher moments has arguments for and against this statement. In part 2.2.2 the specification is given.

1.4 Value at Risk

Value-at-Risk (VaR) is a risk metric developed simultaneously by Markowitz (1952) and Roy (1952) to calculate how much money an investment, portfolio, department or institution such as a bank could lose in a market downturn, though in this period it remained mostly a theoretical discussion due to lacking processing power and industry demand for risk management measures. Another important document in literature is the *1996 RiskMetrics Technical Document*, composed by RiskMetrics⁶, Morgan Guaranty Trust Company (1996) (part of JP Morgan), gives a good overview of the computation, but also made use of the name “value-at-risk” over equivalents like “dollars-at-risk” (DaR), “capital-at-risk” (CaR), “income-at-risk” (IaR) and “earnings-at-risk” (EaR). According to Holton (2002) VaR gained traction in the last decade of the 20th century when financial institutions started using it to determine their regulatory capital requirements. A VaR_{99} finds the amount that would be

⁶RiskMetrics Group was the market leader in market and credit risk data and modeling for banks, corporate asset managers and financial intermediaries (Alexander 2008).

the greatest possible loss in 99% of cases. It can be defined as the threshold value θ_t . Put differently, in 1% of cases the loss would be greater than this amount. It is specified as in (1.13). Christofferson2001 puts forth a general framework for specifying VaR models and comparing between two alternatives models.

$$Pr(y_t \leq \theta_t | \Omega_{t-1}) \equiv \phi \quad (1.13)$$

With y_t expected returns in period t , Ω_{t-1} the information set available in the previous period and ϕ the chosen confidence level.

1.5 Conditional Value at Risk

One major shortcoming of the VaR is that it does not provide information on the probability distribution of losses beyond the threshold amount. As VaR lacks subadditivity of different percentile outcomes, [Artzner1998] reject it as a coherent measure of risk. This is problematic, as losses beyond this amount would be more problematic if there is a large probability distribution of extreme losses, than if losses follow say a normal distribution. To solve this issue, they provide a conceptual idea of a Conditional VaR (CVaR) which quantifies the average loss one would expect if the threshold is breached, thereby taking the distribution of the tail into account. Mathematically, a $cVaR_{99}$ is the average of all the VaR with a confidence level equal to or higher than 99. It is commonly referred to as expected shortfall (ES) sometimes and was written out in the form it is used by today by (Bertsimas et al. 2004). It is specified as in (1.14).

To calculate θ_t , VaR and CVaR require information on the expected distribution mean, variance and other parameters, to be calculated using the previously discussed GARCH models and distributions.

$$Pr(y_t \leq \theta_t | \Omega_{t-1}) \equiv \int_{-\infty}^{\theta_t} f(y_t | \Omega_{t-1}) dy_t = \phi \quad (1.14)$$

1. Literature review

With the same notations as before, and f the (conditional) probability density function of y_t .

According to the BIS framework, banks need to calculate both VaR_{99} and $VaR_{97.5}$ daily to determine capital requirements for equity, using a minimum of one year of daily observations (Basel Committee on Banking Supervision 2016). Whenever a daily loss is recorded, this has to be registered as an exception. Banks can use an internal model to calculate their VaRs, but if they have more than 12 exceptions for their VaR_{99} or 30 exceptions for their $VaR_{97.5}$ they have to follow a standardized approach. Similarly, banks must calculate $CVaR_{97.5}$.

1.6 Past literature on the consequences of higher moments for VaR determination

Here comes the discussion about studies that have looked at higher moments and VaR determination. Also a summary of studies that discusses time-varying higher moments, but not a big part, while it is also only a small part of the empirical findings (couple of GARCH-ACD models).

Table 1.2: Higher moments and VaR

Author	Higher moments
Hansen (1994)	Skewness and kurtosis extended ARCH-model
\@harvey1999	Skewness, Effect of higher moments on lower moments
Brooks et al. (2005)	Kurtosis, Time varying degrees of freedom

While it is relatively straightforward to include unconditional higher-moments in VaR and CVaR calculations, it is less simple to do so when the higher moments (in addition to the variance) are time-varying. Hansen (1994) extends the ARCH model to include time-varying moments beyond mean and variance. While mean returns and variance are usually the parameters of most interest, disregarding these higher moments could provide an incomplete description of a conditional distribution. The model proposed by Hansen (1994) allows for skewness and shape parameters to vary in a skewed-t density function through specifying them as functions of their errors

1.6. Past literature on the consequences of higher moments for VaR determination

in previous periods (in an similar way how variance is estimated). Applications on U.S. Treasuries and exchange rates are discussed.

@harvey1999 extends a GARCH(1,1) model to include time varying skewness by estimating it jointly with time varying variance using a skewed t distribution. They find a significant impact of skewness on conditional volatility, suggesting that these moments should be jointly estimated for efficiency. Changes in conditional skewness have an impact on the persistence of volatility shocks. They also find that including skewness causes the leverage effects of variance to disappear. They apply their methods on different stock indices (both developed and emerging) at daily, weekly and monthly frequency.

Brooks et al. (2005) proposes a model based on a t-distribution that allows for both the variance and the degrees of freedom to be time-varying, independently from each other. Their model allows for both asymmetric variance and kurtosis through an indicator function (which has a positive effect on these moments only when the shock is in the right tail). They apply their model on different financial assets in the U.S. and U.K. at daily frequency.

2

Data and methodology

2.1 Data

We worked with daily returns on the Euro Stoxx 50 Price Index¹ denoted in EUR from 01 January, 1987 to 27 April, 2021. It is the leading blue-chip index of the Eurozone, was founded in 1999 and covers 50 of the most liquid and largest (in terms of free-float market capitalization) stocks. For its composition and computation we refer to the factsheet (*Calculation guide STOXX ®* 2020). The Euro Stoxx 50 Price index was chosen while this one has more data available (going back to 1987).

Table 2.1 provides the main statistics describing the return series analyzed. Let daily returns be computed as $R_t = 100 (\ln P_t - \ln P_{t-1})$, where P_t is the index price at time t and P_{t-1} is the index price at $t - 1$.

The arithmetic mean of the series is 0.017% with a standard deviation of 1.307% and a median of 0.036 which translate to an annualized mean of 4.208% and an annualized standard deviation of 20.748%. The skewness statistic is highly significant and negative at -0.31 and the excess kurtosis is also highly significant

¹The same analysis has been performed for the INDEX 1, INDEX 2, INDEX 3 and the INDEX 4 indexes with the same conclusions. The findings of these researches are available upon requests.

and positive at 7.207. These 2 statistics give an overview of the distribution of the returns which has thicker tails than the normal distribution with a higher presence of left tail observations. A formal test such as the Jarque-Bera one with its statistic at 10429.919 and a high statistical significance, confirms the non normality feeling given by the Skewness and Kurtosis.

Table 2.1: Summary statistics of the returns

Statistics	Euro Stoxx 50	Standardized Residuals
Arithmetic Mean	0.0167	-0.0409
Median	0.0358	-0.0192
Maximum	10.4376	5.7128
Minimum	-13.2404	-11.7738
Stdev	1.307	0.9992
Skewness	-0.31 (0***)	-0.6326 (0***)
Excess Kurtosis	7.2071 (0***)	5.1341 (0***)
Jarque-Bera	19520.3072***	10429.9193***

Notes

¹ This table shows the descriptive statistics of the daily percentage returns of EURO STOXX 50 over the period 1987-01-02 to 2021-04-27 (8953 observations). Including arithmetic mean, median, maximum, minimum, standard deviation. The skewness, excess kurtosis with p-value and significance and the Jarque-Bera test with significance.

² The standardized residual is derived from a maximum likelihood estimation (simple GARCH model) as follows:

$$R_t = \alpha_0 + \alpha_1 R_{t-1} + z_t \sigma_t$$

$$\sigma_t^2 = \beta_0 + \beta_1 \sigma_{t-1}^2 z_{t-1}^2 + \beta_2 \sigma_{t-1}^2,$$

Where z is the standard residual (assumed to have a normal distribution).

³ *, **, *** represent significance levels at the 5

The right column of table 2.1 displays the same descriptive statistics but for the standardized residuals obtained from a simple GARCH model as mentioned in table 2.1 in Note 2. Again, Skewness statistic at -0.633 with a high statistical significance level and the excess Kurtosis at 5.134 also with a high statistical significance, suggest a non normal distribution of the standardized residuals and the Jarque-Bera statistic

2. Data and methodology

at 19520.307, given its high significance, confirms the rejection of the normality assumption.

As can be seen in figure 2.1 the Euro area equity and later, since 1999 the Euro Stoxx 50, went up during the tech (“dot com”) bubble reaching an ATH of €5464.43. Then, there was a correction to boom again until the burst of the 2008 financial crisis. After which it decreased significantly. With an ATL at 09 March, 2009 of €1809.98. There is an improvement, but then the European debt crisis, with it’s peak in 2010-2012, occurred. From then there was some improvement until the “health crisis”, which arrived in Europe, February 2020. This crisis recovered very quickly reaching already values higher then the pre-COVID crisis level.

Figure 2.1: Euro Stoxx 50 Price Index prices

In figure 2.2 the daily log-returns are visualized. A stylized fact that is observable is the volatility clustering. As can be seen: periods of large volatility are mostly followed by large volatility and small volatility by small volatility.

Figure 2.2: Euro Stoxx 50 Price Index log returns

451 In figure 2.3 you can see a proxy for risk, the rolling volatility over one month (22
 452 trading days) calculated using a rolling window of 252 days. As in figure 2.2, you
 453 can see again the pattern of volatility clustering arise.

Figure 2.3: Euro Stoxx 50 rolling volatility (22 days, calculated over 252 days)

2. Data and methodology

454 In figure 2.4 the density distribution of the log returns are examined. As can be seen,
455 as already mentioned in part 1.1, log returns are not really normally distributed.

Figure 2.4: Density vs. Normal Euro Stoxx 50 log returns)

456 In figure 2.5 the prediction errors (in absolute values and squared) are visualized
 457 in autocorrelation function plots. It is common practice to check this, while in
 458 GARCH models the variance is for a large extent driven by the square of the
 459 prediction errors. The first component² α_0 is set equal to the sample average.
 460 As can be seen there is presence of large positive autocorrelation. This reflects,
 461 again, the presence of volatility clusters.

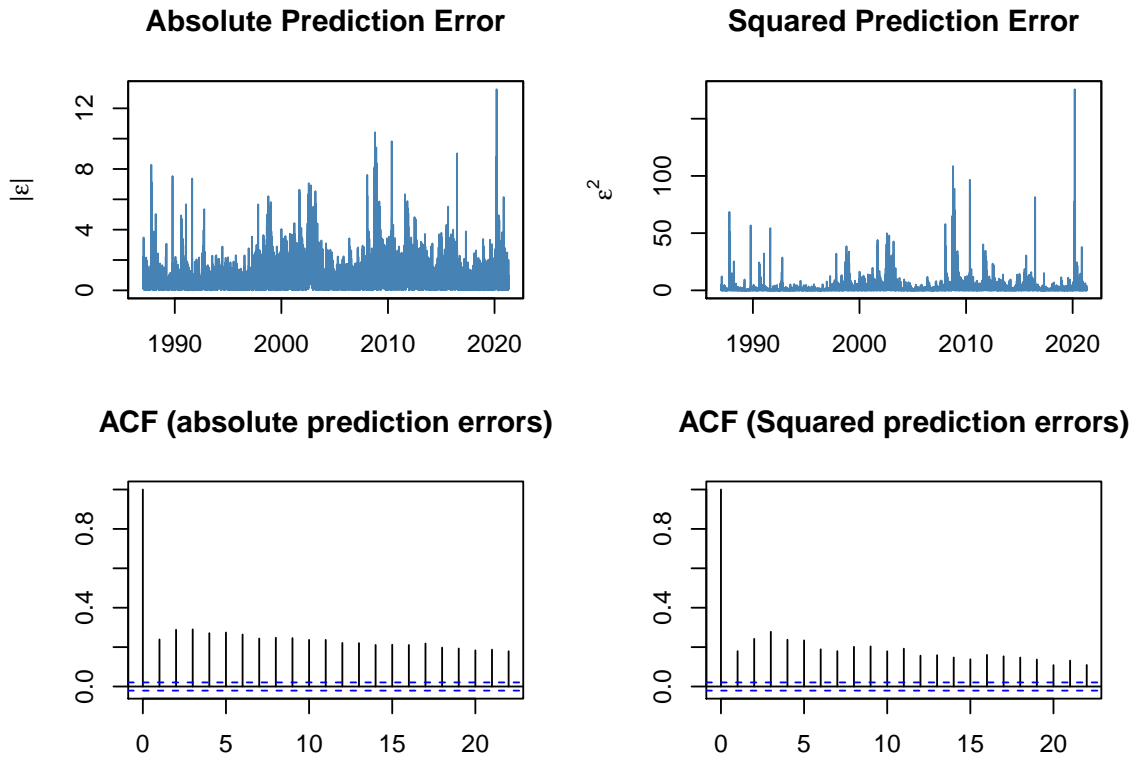

Figure 2.5: Absolute prediction errors

² α_0 is most of the time referred to as the μ in the conditional mean equation. Here we have followed Bali, Mo, et al. (2008).

462 2.2 Methodology

463 2.2.1 Garch models

464 As already mentioned in part 1.2.3, the following models: symmetric GARCH,
 465 EGARCH, IGARCH, GJRGARCH, NGARCH, TGARCH and NAGARCH (or
 466 TSGARCH) will be estimated. Additionally the distributions will be examined as
 467 well, including the normal, student-t distribution, skewed student-t distribution,
 468 generalized error distribution, skewed generalized error distribution and the skewed
 469 generalized t distribution. They will be estimated using maximum likelihood³.

470

471 Maximum likelihood estimation is a method to find the distribution parameters
 472 that best fit the observed data, through maximization of the likelihood function, or
 473 the computationally more efficient log-likelihood function (by taking the natural
 474 logarithm). It is assumed that the return data is i.i.d. and that there is some
 475 underlying parametrized density function f with one or more parameters that
 476 generate the data, defined as a vector θ in equation (2.2). These functions are
 477 based on the joint probability distribution of the observed data as in equation
 478 (2.3). Subsequently, the (log)likelihood function is maximized using an optimization
 479 algorithm shown inequation (2.4).

$$y_1, y_2, \dots, y_N \sim i.i.d \quad (2.1)$$

$$y_i \sim f(y|\theta) \quad (2.2)$$

$$L(\theta) = \prod_{i=1}^N f(y_i|\theta) \quad (2.3)$$

$$\log(L(\theta)) = \sum_{i=1}^N \log f(y_i|\theta)$$

³As already mentioned, fortunately, Ghalanos (2020b) has made it easy for us to implement this methodology in the R language⁴ (R Core Team 2019) with the package “rugarch” v.1.4-4 (*R univariate garch*), which gives us a bit more time to focus on the results and the interpretation.

$$\theta^* = \arg \max_{\theta} [L] \quad (2.4)$$

$$\theta^* = \arg \max_{\theta} [\log(L)]$$

2.2.2 ACD models

Following Ghalanos (2016), arguments of ACD models are specified as in Hansen (1994). The density function $f(y|\alpha)$ has parameters $\alpha_t = (\mu_t, \sigma_t, \nu_t)$, with equation (2.5), the conditional mean equation. Equation (2.6) as the conditional variance. And $\nu_t = \nu(\theta, x_t)$ the remaining parameters of the distribution like the skewness and kurtosis (shape) parameters.

$$\mu_t = \mu(\theta, x_t) = E(y_t | x_t) \quad (2.5)$$

$$\sigma_t^2 = \sigma^2(\theta, x_t) = E\left((y_t - \mu_t^2) | x_t\right) \quad (2.6)$$

To further explain the difference between GARCH and ACD. The scaled innovations are given by equation (2.7). The conditional density is given by equation (2.8) and related to the density function $f(y|\alpha)$ as in equation (2.2.2).

$$z_t(\theta) = \frac{y_t - \mu(\theta, x_t)}{\sigma(\theta, x_t)} \quad (2.7)$$

$$g(z | \eta_t) = \frac{d}{dz} P(z_t < z | \eta_t) \quad (2.8)$$

$$f(y_t | \mu_t, \sigma_t^2, \eta_t) = \frac{1}{\sigma_t} g(z_t | \eta_t) \quad (2.9)$$

489

490 Again Ghalanos (2016) makes it easier to implement the somewhat complex
491 ACD models using the R language with package “racd”.

492 **2.2.3 Analysis Tests VaR and cVaR**

493 **Unconditional coverage test of Kupiec (1995)**

494 A number of tests are computed to see if the value-at-risk estimations capture the
495 actual losses well. A first one is the unconditional coverage test by Kupiec (1995).
496 The unconditional coverage or proportion of failures method tests if the actual
497 value-at-risk exceedances are consistent with the expected exceedances (a chosen
498 percentile, e.g. 1% percentile) of the VaR model. Following Kupiec (1995) and
499 Ghalanos (2020a), the number of exceedances follow a binomial distribution (with
500 thus probability equal to the significance level or expected proportion) under the
501 null hypothesis of a correct VaR model. The test is conducted as a likelihood ratio
502 test with statistic like in equation (2.10), with p the probability of an exceedence
503 for a confidence level, N the sample size and X the number of exceedences. The
504 null hypothesis states that the test statistic LR^{uc} is χ^2 -distributed with one degree
505 of freedom or that the probability of failure \hat{p} is equal to the chosen percentile α .

$$LR^{uc} = -2 \ln \left(\frac{(1-p)^{N-X} p^X}{\left(1 - \frac{X}{N}\right)^{N-X} \left(\frac{X}{N}\right)^X} \right) \quad (2.10)$$

506 **Conditional coverage test of Christoffersen et al. (2001)**

507 Christoffersen et al. (2001) proposed the conditional coverage test. It is tests for
508 unconditional coverage and serial independence. The serial independence is important
509 while the LR^{uc} can give a false picture while at any point in time it classifies
510 inaccurate VaR estimates as “acceptably accurate” (Bali and Theodossiou 2007). For
511 a certain VaR estimate an indicator variable, $I_t(\alpha)$, is computed as equation (2.11).

$$I_t(\alpha) = \begin{cases} 1 & \text{if exceedence occurs} \\ 0 & \text{if no exceedence occurs} \end{cases} . \quad (2.11)$$

512 It involves a likelihood ratio test's null hypothesis is that the statistic is χ^2 -
 513 distributed with two degrees of freedom or that the probability of violation \hat{p}
 514 (unconditional coverage) as well as the conditional coverage (independence) is
 515 equal to the chosen percentile α . While it tests both unconditional coverage as
 516 independence of violations, only this test has been performed and the unconditional
 517 coverage test is not reported.

518 **Dynamic quantile test**

519 **engle2004** provides an alternative test to specify if a VaR model is appropriately
 520 specified by proposing the dynamic quantile test. This test specifies the occurrence
 521 of an exceedence (here hit) as in (2.12), with $I(\cdot)$ a function that indicates when
 522 there is a hit, based on the actual return being lower than the predicted VaR. θ
 523 is the confidence level. They test jointly H_0 that the expected value of hit is zero
 524 and that it is uncorrelated with any variables known at the beginning of the period
 525 (B), notably the current VaR estimate and hits in previous periods, specified as
 526 lagged hits. This is done by regressing hit on these variables as in (2.13). $X\delta$
 527 corresponds to the matrix notation. Under H_0 , this regression should have no
 528 explanatory power. As a final step, a χ^2 -distributed test statistic with m degrees
 529 of freedom equal to the parameters to be estimated (constant, number of hits and
 530 VaR estimate) is constructed as in (2.14).

$$Hit_t = I(R_t < -VaR_t(\theta)) - \theta, \quad (2.12)$$

$$Hit_t = \delta_0 + \delta_1 Hit_{t-1} + \dots + \delta_p Hit_{t-p} + \delta_{p+1} VaR_t + \delta_{p+2} I_{year1,t} + \dots + \delta_{p+2+n} I_{yearn,t} + u_t \quad (2.13)$$

2. Data and methodology

$$Hit_t = X\delta + u_t \quad u_t = \begin{cases} -\theta & \text{prob } (1 - \theta) \\ (1 - \theta) & \text{prob } \theta \end{cases}$$

$$\frac{\hat{\delta}'_{OLS} X' X \hat{\delta}_{OLS}^a}{\theta(1 - \theta)} \sim \chi^2(m) \quad (2.14)$$

3

Empirical Findings

3.1 Density of the returns

3.1.1 MLE distribution parameters

In table ?? we can see the estimated parameters of the unconditional distribution functions. They are presented for the Skewed Generalized T-distribution (SGT) and limiting cases thereof previously discussed. Additionally, maximum likelihood score and the Aikake Information Criterion (AIC) is reported to compare goodness of fit of the different distributions. We find that the SGT-distribution has the highest maximum likelihood score of all. All other distributions have relatively similar likelihood scores, though slightly lower and are therefore not the optimal distributions. However, when considering AIC it is a tie between SGT and SGED. This provides some indication that we have a valid case to test the suitability of different SGED-GARCH VaR models as an alternative for the SGT-GARCH VaR models. While sacrificing some goodness of fit, the SGED distribution has the advantage of requiring one less parameter, which could possibly result in less errors due to misspecification and easier implementation. For the SGT parameters the standard deviation and skewness are both significant at the 1% level. For the SGED parameters, the standard deviation and the skewness are both significant

3. Empirical Findings

at respectively the 1% and 5% level. Both distributions are right-skewed. For both distributions the shape parameters are significant at the 1% level, though the q parameter was not estimated as it is by design set to infinity due to the SGED being a limiting case of SGT.¹

Additionally, for every distribution fitted with MLE, plots are generated to compare the theoretical distribution with the observed returns. We see that except for the normal distribution which is quite off, the theoretical distributions are close to the actual data, except that they are too peaked. This problem is the least present for the SGT distribution.

¹To check whether the relative ranking of distributions still holds in different periods, we have calculated the maximum likelihood score and AIC for three smaller periods: The period up to the dotcom collapse (1987-2001), up to the GFC (2002-2009) and up to the present Covid-crash (2009-2021). There is no qualitative difference in relative ranking with these subsamples. Results are reported in the appendix.

3.2 Constant higher moments

3.1 presents the maximum likelihood estimates for 8 symmetric and asymmetric GARCH models based on the ST distribution with constant skewness and kurtosis parameters (t values are presented in parenthesis). The parameters in the conditional mean equations (α_0) are all statistically significant with t values from 6 to 11. The AR(1) coefficient, α_1 , has parameters going from 2 to 2 with t values ranging from 4 to 5 not suggesting a high significance and indicating slight negative autocorrelation. The GARCH parameters in the conditional variance equations (β_0) are generally statistically significant with t values ranging from 1 to 11. The results of β_1 and β_2 show the presence of significant time-variation in the conditional volatility of the Euro Stoxx 50 Price Index daily returns, in fact, the sum of β_1 and β_2 for the GARCH parameters is close to one (from 20 to 33), suggesting the presence of persistence in the volatility of the returns. The parameter ξ is highly significant for all the 8 models tested with values ranging from 12 to 18 confirming the presence of Skewness in the returns. The shape parameter η , which, in our case, measures the number of degrees of freedom, determining the tail behavior, is significant for all the models and ranges between 14 and 19. The parameter γ , which is present only for eGARCH and gjrGARCH is significant and with values around 4.5. The absolute value function in fGARCH models (NAGARCH, TGARCH and AVGARCH) is subject to the *shift* and the *rot* parameters whose values are always positive and statistically significant. According to the log likelihood values (LLH), displayed in 3.1, the model with the highest value is eGARCH while, excluding the non-standard GARCH models from the analysis, the model that performs best is eGARCH.

3. Empirical Findings

Table 3.1: Maximum likelihood estimates of the ST-GARCH models with constant skewness and kurtosis parameters

	SGARCH	IGARCH	EGARCH	GJRARCH	EWMA	NAGARCH	TGARCH	AVGARCH
α_0	0.049 (5.281)	0.049 (5.195)	0.026 (2.762)	0.028 (3.026)	0.053 (5.855)	0.02 (2.15)	0.023 (2.394)	0.018 (2.292)

Notes

This table shows the maximum likelihood estimates of various ST-GARCH models. The daily returns used on the Euro Stoxx 50 Price index cover the period from 02 January, 1987 to 27 April, 2021 (8953 observations).

The mean process is modeled as follows: $R_t = \alpha_0 + \alpha_1 \times R_{t-1} + \varepsilon_t$

Where, in the 8 GARCH models estimated, γ is the asymmetry in volatility, ξ , κ and η are constant and t statistics are displayed in parenthesis.

LLH is the maximized log likelihood value.

As you can see in table 3.2 the AIC for the skewed student's t-distribution (ST) is the best from all the models. As also shown in appendix part B. The best in all distributions of the GARCH models seems to be the NAGARCH model, but we do not want to overfit our models because of an in-sample estimation. That is why a parsimonious model like the EGARCH (which has the highest maximum likelihood for the standard GARCH models that are considered), but also the model AVGARCH will be examined using the ST distribution while it has the second-best (lowest) AIC.

Table 3.2: Model selection according to AIC

	SGARCH	IGARCH	EWMA	EGARCH	GJRGARCH	NAGARCH	TGARCH	AVGARCH
norm	2.995	2.998	3.034	2.962	2.967	2.955	2.957	2.955
std	2.924	2.924	2.935	2.900	2.905	2.897	2.896	2.896

ged	2.930	2.931	2.945	2.907	2.911	2.903	7.704	7.701
sged	2.927	2.928	2.940	2.902	2.907	2.898	7.675	7.672

Notes

¹ This table shows the AIC value for the respective model

3. Empirical Findings

589 3.2.1 Value-at-risk

590 As already mentioned 2 candidate models seem to be very appropriate. This includes
591 the EGARCH and the NAGARCH So to check if they perform well out-of-sample
592 we conduct a backtest by using a rolling forecasting technique. A simple graph is
593 shown in figure 3.1 for the EGARCH-ST model. It seems that the VaR model for
594 $\alpha = 0.05$ underestimates the downside events, while the VaR model for $\alpha = 0.01$
595 captures more of the downside events.

Figure 3.1: Value-at-Risk (in-sample) for the EGARCH-ST model

596 Let us examine this further using a rolling window approach whilst forecasting
597 1-day ahead results with re-estimating parameters every year.

598 **[Note for prof. Annaert: choices:**

- 599 – `n.start = 2500` ==> sample = 2500 observations to forecast the next,
- 600 – `refit.every = 252` (trading days in a year) ==> so recompute the parameters
- 601 every year,
- 602 – `solver = hybrid` using `cluster = 10` to run on 10 cores to speed up the process
- 603 of estimation of the roll object (took 5-10 minutes per backtest with some solvers,
- 604 now with parallel package. . .)
- 605 – `forecast.length = 1` ==> length of total forecast for which out of sample data
- 606 from dataset will be used for testing |

3.2. Constant higher moments

607 Figure 3.2 shows that choosing an appropriate forecast period is important
608 (with here the Eurobond crisis, the Brexit and Covid-crisis), so in order to avoid
609 a look-ahead bias this rolling window approach was used.

3. Empirical Findings

Figure 3.2: Selected period to start forecast from

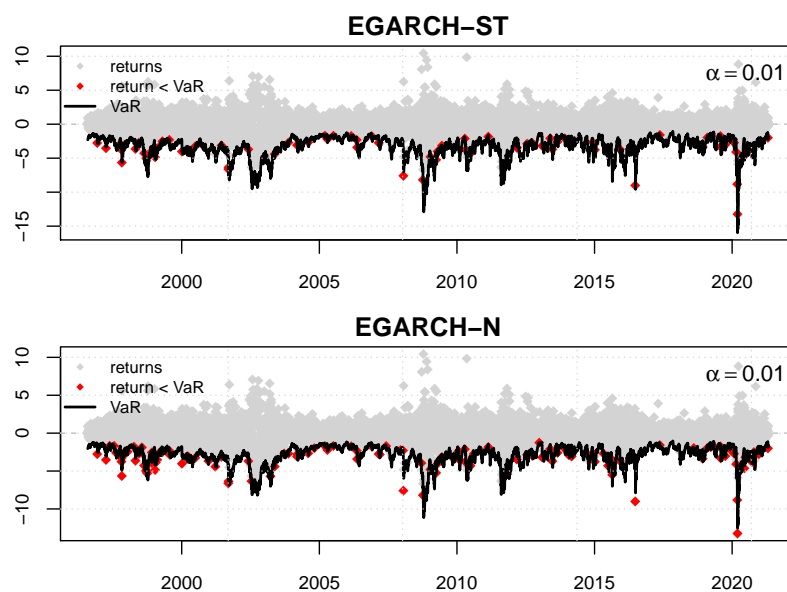

Figure 3.3: Comparison between VaR-EGARCH-ST and VaR-NAGARCH-N

610 As you can see in figure ?? the EGARCH with a normal distribution seems
 611 to capture the extreme events a bit less compared with the skewed t-distribution.
 612 But let us formally test this.

Robustness checks

4.1 Specification checks

In order to check if the models are specified correctly, some specification checks have to be performed. The specification checks have to be done on the standardized residuals of the estimated GARCH model given by the following equation:

$$\hat{Z}_t = \frac{\hat{\varepsilon}_t}{\hat{\sigma}_t} = \frac{R_t - \hat{\mu}}{\hat{\sigma}_t}$$

Figures control tests Autocorrelation function of the standardized residuals and autocorrelation function of the squared standardized residuals.

Then the density can be examined standardized residuals and compared with the normal distribution.

Also the QQ-plot can be examined.

4.1.1 Residual heteroscedasticity

Ljung-Box test on the squared or absolute standardized residuals.

zero-mean unit-variance not skewed no excess kurtosis no serial correlation in the squares no serial correlation in the cubes no serial correlation in the squares

Alternatives to the normal distribution

SGT (Skewed Generalized t-distribution) The SGT distribution is introduced by Theodossiou (1998) and applied by Bali and Theodossiou (2007) and Bali, Mo, et al. (2008). According to Bali, Mo, et al. (2008) the proposed solutions (use of historical simulation, student's t-distribution, generalized error distribution or a mixture of two normal distributions) to the non-normality of standardized financial returns only partially solved the issues of accounting for skewness and leptokurtosis. The Pdf of the SGT distribution is given by equation (A.1). B is the beta function (also called Euler integral).

$$f_{SGT}(x; \mu, \sigma, \xi, \kappa, \eta) = \frac{\kappa}{2v\sigma\eta^{1/\kappa} B\left(\frac{1}{\kappa}, \eta\right) \left(\frac{|x-\mu+m|^\kappa}{\eta(v\sigma)^\kappa (\xi \text{sign}(x-\mu+m)+1)^\kappa + 1} \right)^{\frac{1}{\kappa} + \eta}}$$

$$m = \frac{2v\sigma\xi\eta^{\frac{1}{\kappa}} B\left(\frac{2}{\kappa}, \eta - \frac{1}{\kappa}\right)}{B\left(\frac{1}{\kappa}, \eta\right)} \quad (\text{A.1})$$

$$v = \frac{\eta^{-\frac{1}{\kappa}}}{\sqrt{(3\xi^2+1) \frac{B\left(\frac{3}{\kappa}, \eta - \frac{2}{\kappa}\right)}{B\left(\frac{1}{\kappa}, \eta\right)} - 4\xi^2 \frac{B\left(\frac{2}{\kappa}, \eta - \frac{1}{\kappa}\right)^2}{B\left(\frac{1}{\kappa}, \eta\right)^2}}}$$

A. Appendix to literature review

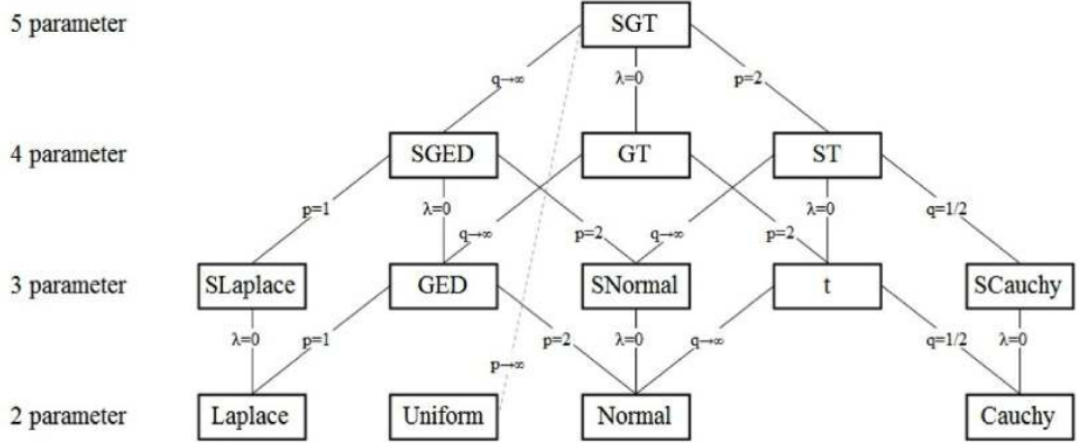

Figure A.1: SGT distribution and limiting cases

643 Following Theodossiou (1998) however, there are two parameters, κ^1 and η^2) for the
644 shape in the SGT distribution. κ is the peakedness parameter. η is the tail-thickness
645 parameter. It is equal to the degrees of freedom ν divided by 2 if $\xi = 0$ and $\kappa = 2$.
646 As shown in the following figure³ A.1 by Carter Davis, from the SGT the other
647 distributions in the figure are limiting cases of the SGT.

648 **Student's t-distribution** A common alternative for the normal distribution is
649 the Student t distribution. Similarly to the normal distribution, it is also symmetric
650 (skewness is equal to zero if $\nu > 3$). The probability density function (pdf),
651 consistent with Ghalanos (2020a), is given by equation (A.2). As will be seen in
652 1.2, GARCH models are used for volatility modeling in practice. Bollerslev (1987)
653 examined the use of the GARCH-Student or GARCH-t model as an alternative
654 to the standard Normal distribution, which relaxes the assumption of conditional
655 normality by assuming the standardized innovation to follow a standardized Student
656 t-distribution (Bollerslev 2008).

¹Referred to as κ by Theodossiou (1998) and Bali, Mo, et al. (2008), but p by Carter Davis in the “sgt” package.

²Also referred to as n by Theodossiou (1998) and η by Bali, Mo, et al. (2008), but q by Carter Davis in the “sgt” packages.

³Source: <https://cran.r-project.org/web/packages/sgt>

$$f(x; \mu, \sigma, \nu) = \frac{\Gamma(\frac{\nu+1}{2})}{\Gamma(\frac{\nu}{2})\sqrt{\sigma\pi\nu}} \left(1 + \frac{(x-\mu)^2}{\sigma\nu}\right)^{-(\nu+1)/2} \quad (\text{A.2})$$

where μ, σ and ν are respectively the mean, scale and shape (tail-thickness) parameters. $\nu/2$ is equal to the η^4 parameter of the SGT distribution with other restrictions (see part A). The symbol Γ is the Gamma function.

Unlike the normal distribution, which depends on two parameters only, the student t distribution allows for fatter tails. This kurtosis coefficient is given by equation (A.3) if $\nu > 4$. This is useful while the standardized residuals of stock returns appear to have fatter tails than the normal distribution following Bollerslev (2008).

$$kurt = 3 + \frac{6}{\nu - 4} \quad (\text{A.3})$$

Generalized Error Distribution The GED distribution is nested in the generalized t distribution by McDonald and Newey (1988) and is used in the GED-GARCH model by Nelson (1991) to model stock market returns. This model replaced the assumption of conditional normally distributed error terms by standardized innovations that following a generalized error distribution. It is a symmetric, unimodal distribution (location parameter is the mode, median and mean). This is also sometimes called the exponential power distribution (Bollerslev 2008). The conditional density (pdf) is given by equation (A.4) following Ghalanos (2020a).

$$f(x; \mu, \sigma, \kappa) = \frac{\kappa e^{-\frac{1}{2}\left|\frac{x-\mu}{\sigma}\right|^\kappa}}{2^{1+1/\kappa}\sigma\Gamma(1/\kappa)} \quad (\text{A.4})$$

where μ, σ and κ are respectively the mean, scale and shape parameters.

⁴Also referred to as n by Theodossiou (1998) or q by Carter Davis in the “sgt” package.

A. Appendix to literature review

Skewed t-distribution The density function can be derived following Fernández and Steel (1998) who showed how to introduce skewness into uni-modal standardized distributions (Trottier and Ardia 2015). The first equation from Trottier and Ardia (2015), here equation (A.5) presents the skewed t-distribution.

$$f_{\xi}(z) \equiv \frac{2\sigma_{\xi}}{\xi + \xi^{-1}} f_1(z_{\xi}), \quad z_{\xi} \equiv \begin{cases} \xi^{-1}(\sigma_{\xi}z + \mu_{\xi}) & \text{if } z \geq -\mu_{\xi}/\sigma_{\xi} \\ \xi(\sigma_{\xi}z + \mu_{\xi}) & \text{if } z < -\mu_{\xi}/\sigma_{\xi} \end{cases} \quad (\text{A.5})$$

where $\mu_{\xi} \equiv M_1(\xi - \xi^{-1})$, $\sigma_{\xi}^2 \equiv (1 - M_1^2)(\xi^2 + \xi^{-2}) + 2M_1^2 - 1$, $M_1 \equiv 2 \int_0^{\infty} u f_1(u) du$ and ξ between 0 and ∞ . $f_1(\cdot)$ is in this case equation (A.2), the pdf of the student t distribution coming to equation (A.6), which has the parameterization following the SGT parameters.

$$f_{ST}(x; \alpha, \beta, \xi, \eta) = \frac{\Gamma(\frac{1}{2} + \eta)}{\sqrt{\beta\pi\eta}\Gamma(\eta) \left(\frac{|x - \alpha + m|^2}{\eta\beta(\xi \operatorname{sign}(x - \alpha + m) + 1)^2} + 1 \right)^{\frac{1}{2} + \eta}} \quad (\text{A.6})$$

$$m = \frac{2\xi\sqrt{\beta\eta}\Gamma(\eta - \frac{1}{2})}{\sqrt{\pi}\Gamma(\eta + \frac{1}{2})}$$

According to Giot and Laurent (2003) as well as Giot and Laurent (2004), the skewed t-distribution outperforms the symmetric density distributions.

Skewed Generalized Error Distribution A further distribution to analyse is the SGED distribution of Theodossiou (2000). It is applied in GARCH models by Lee et al. (2008). The SGED distribution extends the Generalized Error Distribution (GED) to allow for skewness and leptokurtosis. The density function can be derived following Fernández and Steel (1998) who showed how to introduce skewness into uni-modal standardized distributions (Trottier and Ardia 2015). It can also be found in Theodossiou (2000). The pdf is then given by the same equation (A.5) as the skewed t-distribution but with $f_1(\cdot)$ equal to equation (A.4). To then get equation (A.7).

$$f_{SGED}(x; \mu, \sigma, \xi, \kappa) = \frac{\kappa e^{-\left(\frac{|x-\mu+m|}{v\sigma(1+\xi \operatorname{sig}(x-\mu+m))}\right)^\kappa}}{2\nu\sigma\Gamma(1/\kappa)}$$

$$m = \frac{2^{\frac{2}{\kappa}} \nu \sigma \xi \Gamma\left(\frac{1}{2} + \frac{1}{\kappa}\right)}{\sqrt{\pi}} \quad (\text{A.7})$$

$$v = \sqrt{\frac{\pi \Gamma\left(\frac{1}{\kappa}\right)}{\pi(1+3\xi^2)\Gamma\left(\frac{3}{\kappa}\right) - 16^{\frac{1}{\kappa}} \lambda^2 \Gamma\left(\frac{1}{2} + \frac{1}{\kappa}\right)^2 \Gamma\left(\frac{1}{\kappa}\right)}}$$

691 GARCH models

692 All the GARCH models are estimated using the package “rugarch” by Ghalanos
693 (2020b). We use specifications similar to Ghalanos (2020a). Parameters have to be
694 restricted so that the variance output always is positive, except for the EGARCH
695 model, as this model mathematically ensures the output is positive.

696 **Symmetric (normal) GARCH model** The standard GARCH model (Bollerslev
697 1986) is written consistent with Ghalanos (2020a) as in equation (A.8) without
698 external regressors.

$$\sigma_t^2 = \beta_0 + \beta_1 \varepsilon_{t-j}^2 + \beta_2 \sigma_{t-j}^2 \quad (\text{A.8})$$

699 where σ_t^2 denotes the conditional variance, β_0 the intercept and ε_t^2 the residuals from
700 the used mean process. The GARCH order is defined by (q, p) (ARCH, GARCH),
701 which is here $(1, 1)$. As Ghalanos (2020a) describes: "one of the key features of
702 the observed behavior of financial data which GARCH models capture is volatility
703 clustering which may be quantified in the persistence parameter \hat{P} specified as in
704 equation (A.9) for a GARCH model of order $(1, 1)$.

$$\hat{P} = \beta_1 + \beta_2. \quad (\text{A.9})$$

A. Appendix to literature review

705 The unconditional variance of the standard GARCH model of Bollerslev is very
706 similar to the ARCH model, but with the Garch parameter (β_2) included as
707 in equation (A.10).

$$\begin{aligned}\hat{\sigma}^2 &= \frac{\beta_0}{1 - \hat{P}} \\ &= \frac{\beta_0}{1 - \beta_1 - \beta_2}\end{aligned}\tag{A.10}$$

708 **IGARCH model** Following Ghalanos (2020a), the integrated GARCH model
709 (Bollerslev 1986) can also be estimated. This model assumes the persistence
710 $\hat{P} = 1$. This is done by Ghalanos, by setting the sum of the ARCH and GARCH
711 parameters to 1. Because of this unit-persistence, the unconditional variance
712 cannot be calculated.

713 **GJRGARCH model** The GJRGARCH model (Glosten et al. 1993), which
714 is an alternative for the asymmetric GARCH (AGARCH) by Engle (1990) and
715 Engle and Ng (1993), models both positive as negative shocks on the conditional
716 variance asymmetrically by using an indicator variable $I_t - 1$, it is specified as
717 in equation (A.11).

$$\sigma_t^2 = \beta_0 + \beta_1 \varepsilon_{t-1}^2 + \gamma_j I_{t-1} \varepsilon_{t-1}^2 + \beta_2 \sigma_{t-1}^2\tag{A.11}$$

718 where γ_j represents the *leverage* term. The indicator function I takes on value
719 1 for $\varepsilon \leq 0$, 0 otherwise. Because of the indicator function, persistence of the
720 model now crucially depends on the asymmetry of the conditional distribution
721 used according to Ghalanos (2020a).

722 **EGARCH model** The EGARCH model or exponential GARCH model (Nelson
723 1991) is defined as in equation (A.12). The advantage of the EGARCH model is
724 that there are no parameter restrictions, since the output is log variance (which
725 cannot be negative mathematically), instead of variance.

$$\log_e(\sigma_t^2) = \beta_0 + \beta_1 z_{t-1} + \gamma_1(|z_{t-1}| - E|z_{t-1}|) + \beta_2 \log_e(\sigma_{t-j}^2) \quad (\text{A.12})$$

726 where β_1 captures the sign effect and γ_j the size effect.

727 **NAGARCH model** The NAGARCH or nonlinear asymmetric model (Engle
728 and Ng 1993). It is specified as in equation (A.13). The model is *asymmetric* as it
729 allows for positive and negative shocks to differently affect conditional variance and
730 *nonlinear* because a large shock is not a linear transformation of a small shock.

$$\sigma_t^2 = \beta_0 + \beta_1(\varepsilon_{t-1} + \gamma_1\sqrt{\sigma_{t-1}})^2 + \beta_2\sigma_{t-1}^2 \quad (\text{A.13})$$

731 As before, γ_1 represents the *leverage* term.

732 **TGARCH model** The TGARCH or threshold model (Zakoian 1994) also models
733 asymmetries in volatility depending on the sign of the shock, but contrary to the
734 GJRGARCH model it uses the conditional standard deviation instead of conditional
735 variance. It is specified as in (A.14).

$$\sigma_t = \beta_0 + \beta_1^+ \varepsilon_{t-1}^+ \beta_1^- + \varepsilon_{t-1}^- + \beta_2 \sigma_{t-1} \quad (\text{A.14})$$

736 where ε_{t-j}^+ is equal to ε_{t-j} if the term is negative and equal to 0 if the term is
737 positive. The reverse applies to ε_{t-j}^- . They cite Davidian and Carroll (1987) who
738 find that using volatility instead of variance as scaling input variable gives better
739 variance estimates. This is due to absolute residuals (contrary to squared residuals
740 with variance) more closely predicting variance for non-normal distributions.

A. Appendix to literature review

741 **TSGARCH model** The absolute value Garch model or TS-Garch model, as
742 named after Taylor (1986) and Schwert (1989), models the conditional standard
743 deviation and is intuitively specified like a normal GARCH model, but with the
744 absolute value of the shock term. It is specified as in (A.15).

$$\sigma_t = \beta_0 + \beta_1 |\varepsilon_{t-1}| + \beta_2 \sigma_{t-1} \quad (\text{A.15})$$

745 **EWMA** An alternative to the series of GARCH models is the exponentially
746 weighted moving average or EWMA model. This model calculates conditional
747 variance based on the shocks from previous periods. The idea is that by including
748 a smoothing parameter ξ more weight is assigned to recent periods than distant
749 periods. The ξ must be less than 1. It is specified as in (A.16).

$$\sigma_t^2 = (1 - \xi) \sum_{j=1}^{\infty} (\xi^j \varepsilon_{t-j}^2) \quad (\text{A.16})$$

750 In practice a ξ of 0.94 is often used, such as by the financial risk management com-
751 pany RiskMetricsTM model of J.P. Morgan (Morgan Guaranty Trust Company 1996).

B

Appendix to findings

Goodness of fit

As already mentioned, next to testing the models in part 3, we also tested other models using the different distributions. This we did in order to check if distributions that capture the higher moment effects are really better in terms of goodness of fit. We did a small data mining experiment with 124 models that were estimated. This can ofcourse lead to overfitting because of the fit in-sample. However, we can decide if there is a trend using the different distributions for the several GARCH models. Thus, in this experiment, our rule of thumb was to examine general trends. Six cases were examined.

B. Appendix to findings

First, in figure B.1, symmetric GARCH with symmetric distributions are looked at. As you can see the student's t distribution (T) performs better than general error distribution (GED), that performs better than the normal distribution (NORM) according to both the AIC and BIC. Which is consistent with the literature that found that the assumption of the normal distribution is a rather poor assumption.

Figure B.1: Goodness of fit symmetric GARCH and distributions

769 Second, in figure B.2, symmetric GARCH with the best symmetric distribution (T)
 770 and the other distributions (SGED, ST) are looked at. As you can see consistent with
 771 Giot and Laurent (2003) the skewed student's t (ST) distribution outperforms the
 772 symmetric distributions. It also outperforms in terms of goodness of fit the SGED.

Figure B.2: Goodness of fit symmetric GARCH and other distributions

B. Appendix to findings

773 In figure B.3 you can see the same patter as in figure B.1, the student's t distribution
774 performs best among the symmetric distributions.

Figure B.3: Goodness of fit asymmetric GARCH and symmetric distributions

775 Then, in figure B.4 the same patter arises as in figure B.2, the skewed student's
 776 t distribution again seems to be the most optimal one to use. Therefore the ST
 777 distribution is chosen as final model for the Euro Stoxx 50 index.

Figure B.4: Goodness of fit asymmetric GARCH and symmetric distributions

778 In two additional figures the family garch models (TGARCH, NAGARCH and
 779 AVGARCH) are examined, the same patterns were observed as above¹.

¹Although we have to note that for some models like TGARCH and AVGARCH with SGED distribution the the AIC was double of other models and therefore these models seem to work very poorly or are misspecified.
